ABSTRACT
To compare the effect of NaCl, CaCl₂ and their combinations on germination and early seedling growth stages of Capsicum annum L., two-separated experiments were laid out at Laboratory of the Agric. Botany Dept., Fac. of Agric., Mansoura Univ., Egypt, during the growing season 2008. Results indicated that significant increases were recorded in percentage of germination (GP), germination performance index (GPI), as well as seedling fresh and dry weights, seedling length, water content, catalase (CAT) activity and photosynthetic pigments concentrations (chlorophyll a, b and total chlorophylls as well as carotenoids) under the low level (2000 ppm) of NaCl or CaCl₂ and their combination (1:1). Increasing salt concentration in nutrient cooper solution caused significant decrease in all of these parameters. The great reduction occurred under high salinity level of NaCl (4000 ppm). However, seedling water content (WC) was not significantly decreased. In addition, CaCl₂ at 4000 ppm increased significantly the total carotenoids as compared with NaCl. Meanwhile, peroxidase (POD) activity increased significantly with increasing salinity levels from 2000 to 4000 ppm of both applied salinity types. Moreover, POD activity under NaCl levels showed a marked increase followed by NaCl+ CaCl₂ (1:1) and CaCl₂ at 4000 ppm.

Keywords: Capsicum annum L., salinity, germination, seedling growth, catalase, peroxidase, photosynthetic pigments.

INTRODUCTION
Sweet pepper (Capsicum annum L.) is among the most important crops for the world human nutrition. The arid and semi-arid conditions as well as less availability of fresh water have inflicted the saline conditions in these provinces and are threatening the productivity of this crop, which is considered as moderately sensitive to salt stress (Lycoskoufis et al., 2005). In general, seed germination and early seedling growth are considered as the most sensitive stages to salinity stress (Ashraf and Foolad, 2005) in most of the crops than the growth of established. Seed germination and seedling growth of sweet pepper like other crops, were negatively affected by salinity stress (Khan et al., 2006 and Bassuony et al., 2008). Germination and emergence of pepper seeds are also slow and non-uniform under normal as well as stress conditions (Demir and Okcu, 2004). Soil salinity, if not properly managed, causing decrease in germination rate and germination percentage of pepper seeds.

The salt damage to the seed germination is attributed to various factors such as reduction in water availability, changes in mobilization of stored reserves and affecting structural organization of proteins (Almansouri et al., 2001). The seeds require higher amount of water uptake during the germination under the salt stress due to the accumulation of the soluble
solutes around the seeds, which increases the osmotic pressure. This causes excessive uptake of the ions which results in toxicity in the plant. Moreover, this process that is affected in plants, growing under saline conditions, is photosynthesis. Reduced photosynthesis under salinity is not only attributed to stomata closure leading to a reduction of intercellular CO\textsubscript{2} concentration, but also to non-stomata factors. There is strong evidence that salt affects photosynthetic enzymes, chlorophylls and carotenoids (Stepien and Klobus, 2006). In addition, salinity causing disturbance of membrane integrity (Hasegawa et al., 2000), activities of enzymes and damaged photosynthetic components (Winston, 1990). An important cause of this damage is production of reactive oxygen species (ROS) (Smirnoff, 1993). Moreover, plants have the ability to scavenge/detoxify ROS by producing different types of antioxidants (enzymatic and non-enzymatic). Enzymatic antioxidants such as catalase (CAT), peroxidase (POD), (Prochazkova and Wilhelmova, 2007 and Ashraf, 2009). Therefore, the present study was planned to determine the effects of NaCl, CaCl\textsubscript{2} salinity and their combinations on sweet pepper germination.

**MATERIALS AND METHODS**

The experiment was carried out in the Laboratory of the Agricultural Botany Dept., Fac. of Agriculture, Mansoura Univ. during the growing season 2008, to study the effect of NaCl or CaCl\textsubscript{2} and their combination (1:1 w/w) on germination and early seedling growth stages of sweet pepper (Capsicum annuum L. cv. Orlando), a hybrid ‘California Wonder’. The seeds used in this investigation were secured from the Gohara Co. Cairo, Egypt. Salinity stress was induced by Sodium Chloride (NaCl), Calcium Chloride (CaCl\textsubscript{2}) and their combination, NaCl: CaCl\textsubscript{2} (1:1 w/w) from EL-Gomhoria Co., Egypt and were used at the concentrations of 2000 and 4000 ppm each (Table 1).

A homogenous lot of sweet pepper seeds were placed in 100 ml beakers and 20 ml of 1% sodium hypochlorite was added for sterilization. These were left in the solution for 5 min followed by washing under running tap water and ionized water twice, then soaked (24 hours) in distilled water. After soaking, the sterilized seeds were divided into 7 sets (7 salinity levels), then placed in glass Petri dishes (11 cm) (25 seeds/dish) with a double layer
of Whatman No. 1 filter paper. The first set was moistened with 10 ml nutrient Cooper solution (table 2), (Cooper, 1979) E.C., (2.0 dSm⁻¹) served as control. The six remainder sets were salinized with 10 ml nutrient solution adding salts (Table 1). Measuring the electrical conductivity by digital conductivity meter Lutron CD-4301. The dishes were left in an incubator in the dark for seed germination at 25 ± 2°C and 90% relative humidity, then the dishes were covered with aluminum foils for darkens. In order to avoid water losses, 5 ml of the nutrient solution were added to Petri dishes, every 5 days. Thiram was added to the solution at a concentration of 2% (w/v) to control the fungi infection. The experiment was repeated two times and arranged in a completely randomized block design with three replicates.

Germination percentage was recorded every 24 h for 11 days (ISTA, 1999). Germination performance index (GPI) was calculated according to the formula: GPI= GP/MGT; where GP is germination percentage and MGT is mean time to germination in days (Pill and Fieldhouse, 1982). In the second set of this experiment, the Petri dishes were placed under the laboratory condition at 20 ± 2°C under light (40 W fluorescent tubes) for greening. After 14 days, (end of germination), the following data were recorded:

a. Seedling fresh and dry weight (mg/10 seedling).
b. Seedling length (cm).
c. The seedling water content (WC) expressed as (mg g⁻¹) was calculated from FW and DW values (Song and Fujiyama, 1998) using the following equation: WC = [(FW-DW)/FW] × 1000. Where WC is the water content (mg g⁻¹) ; FW and DW are the fresh weight (mg seedling⁻¹) and dry weight (mg seedling⁻¹) of the seedlings plant, respectively.
d. Enzymatic activity: The enzyme extraction was done as recommended by Maxwell and Bateman (1967). One gram of fresh sample (cotyledons) was ground with 10 ml 0.1 M Na-phosphate buffer at pH 7.1 in a lab mortar. The homogenate was transferred to centrifuge tubes and was centrifuged at 4°C for 15 min at 15000 rpm in laboratory refrigerated
Arafa, A.A. et al.

centrifuges Model SIGMA 4K15. The supernatant was made up to a known volume with the same buffer and used for enzyme assay.

d.1. Peroxidase activity (POD) (EC1.11.1.7): The enzymatic activity of POD was determined with a (Spekoll 11) spectrophotometer. The activity of POD was determined according to the method described by Allam and Hollis (1972). This method depends on measuring the oxidation of pyrogallol to pyrogallin in the presence of hydrogen peroxide (H\textsubscript{2}O\textsubscript{2}) at 425 nm. The sample cuvette contained 500 µl of 0.1 M potassium phosphate buffer (pH 7.0) + 300 µl of 0.05 M pyrogallol (6.3 g/L) + 100 µl of 1.0% H\textsubscript{2}O\textsubscript{2} + 100 µl enzyme extract. Readings were recorded every 30 seconds for 5 minutes at 27±2°C. The activity was expressed as ΔA\textsubscript{410} g\textsuperscript{-1} min\textsuperscript{-1}.

d.2. Catalase activity (CAT) (EC 1.11.1.6): The enzymatic activity of CAT was measured according to Aebi (1984). About 3 ml reaction mixture containing 1.5 ml of 100 mM potassium phosphate buffer (pH 7.0), 0.5 ml of 75 mM H\textsubscript{2}O\textsubscript{2}, 0.05 ml enzyme extraction and distilled water to make up the volume to 3 ml. The reaction started by adding H\textsubscript{2}O\textsubscript{2} and a decrease in absorbance was recorded at 240 nm for 1 min. Enzyme activity was computed by calculating the amount of H\textsubscript{2}O\textsubscript{2} decomposed. Each enzyme activity was expressed as enzyme unit per gram fresh weight of leaf.

e. Photosynthetic pigments (mg/g FW): Fresh leaf samples (0.05 g) were extracted by methanol for 24 h at laboratory temperature after adding a trace from sodium carbonate (Robinson et al., 1983), then Chlorophyll a, b and carotenoids were determined spectrophotometrically (Spekol II) (at wave lengths 452, 650, 665 nm). The quantities of total chlorophylls, chlorophyll a, b and carotenoids concentration (mg/g) in leaves were determined by the equations proposed by Mackiny (1941).

\[
\text{Total Chlorophyll} = (25.5*E_{650} + 4*E_{665})/5 \\
\text{Chlorophyll a} = (16.5*E_{665} - 8.3*E_{650})/5 \\
\text{Chlorophyll b} = (33.8*E_{650} - 12.5*E_{665})/5 \\
\text{Carotenoids} = (4.2 * E_{452.5}) - (0.0264 * \text{Chl. a}) - (0.496 * \text{Chl. b})/5
\]

Statistical analysis: The obtained data were subjected to statistical analysis of variance according to Gomez and Gomez (1984).

RESULTS AND DISCUSSION

1. Germination percentage: The data illustrated in Figures (1, 2) revealed that low levels (2000 ppm) of all of salinity types NaCl, CaCl\textsubscript{2} and their combinations(1:1) increased significantly germination percentage (GP) and germination performance index (GPI). In addition, seeds germinated under NaCl combined with CaCl\textsubscript{2} (1:1) (82.7 %) resulted in a greater germination percentage followed by CaCl\textsubscript{2} and NaCl (81.3 %) as compared to control (74.7 %). The stimulating effects of low level of salinity on GP and GPI may be resulted from the beneficial effect of low Cl\textsuperscript{-} concentration on activities of enzymes (ATPase and α-amylase) which hydrolyse starch to sugars (Metzler, 1977) and dependent the growth of the embryonic axis on the transfer of storage materials from the cotyledons (Glenn et al., 1999). In addition, Na\textsuperscript{+} is an essential micronutrient for some of the C\textsubscript{4} photosynthetic plants, which import pyruvate into mesophyll chloroplasts by a Na\textsuperscript{+}/pyruvate co-transporter (Ohnishi et al., 1990).
The data reveal that GP decreased gradually with increasing salinity from 2000 to 4000 ppm and the great reduction occurred under high salinity level of NaCl (54.7 %). The inhibitory effect of high salinity levels of NaCl and NaCl+ CaCl₂ may be due to increasing osmotic potential which hinder water uptake, an essential initiating step that activates a number of metabolic processes necessary for germination (Kayani et al., 1990) and/or facilitate the intake of ions in sufficient amounts to be toxic for the embryonic activities (Ayers et al., 1952) and/or the influence of the cations more than anions of acid radical used, Cl⁻ is the most toxic acid and Na⁺ is the most toxic base (Bewley and Black, 1982) and/or reduced water availability between the external environment and the seeds also inhibit the primary root emergence (Enéas, Filho et al., 1995) and/or contact of the seeds with high concentrations of Na⁺ and Cl⁻ ions (Almodares et al., 2007) and/or altering hormonal balances and decreasing endogenous cytokinins biosynthesis and auxins productions (Schmidt, 2005) and/or increasing ABA (Roy et al., 1995) and/or effects of salts on the enzymes activities for hydrolysis, translocation of severe hydrolysis products from the storage organs to embryo axis(Ungar, 1995) and/or altered amylase (Kocacaliskan and Kabar, 1990), protease (Prisco and Vierira, 1976) and RNAase (Gomes Filho and Sodek, 1988), and/or decreasing amylase while increasing phenol oxidase activities (Kord and Khalil, 1995).

Generally, this differential behavior of sweet pepper seeds germination according to the salt types are presumably due to the fact that the same concentration of salt generate different osmotic potentials and the osmotic effect may well have a greater influence on germination than specification toxicity (Ungar, 1996).
Arafa, A.A. et al.

Figure (2): Germination performance index (GPI) of sweet pepper under normal or saline condition (NaCl, CaCl$_2$ and their combinations) after 11 days from sowing.

2. Seedling growth: The data illustrated in Figures (3-6) and shown in Plate (1) indicate that fresh and dry weights, seedling length as well as water content after 14 days were increased significantly under low levels 2000 ppm of all salinity types. On the other hand, the increasing salt concentration in nutrient Cooper solution caused significant decrease in fresh and dry weights as well as seedling length but seedling water content showed no-significant effect. The great reduction occurred under high salinity level of NaCl. In the present investigation, Reduced seedling length under saline condition may be due to accumulation of toxic ions, that facilitates the intake ions in sufficient amounts to be toxic for the embryonic activities due to the influence of the cations more anions, the entry of ions to the seeds that might have been toxic to the embryo or the developing seedlings (Almodares et al., 2007) and/or inhibition of the uptake of several essential nutrients causing nutritional or ionic imbalance (Taamali et al., 2004) and/or disturbance in metabolic metabolism leading to an increase in phenolic compounds (Ayaz, et al., 2000) and/or which led to decreasing both cell division and cell elongation.

Salinity induced osmotic cell enlargement depending on soluble accumulation and its effect on cell size and number of cells per unit area (Greenway, 1963). The bad effects of salinity on seedling shoot and root length may be due to the negative effects of salinity on meristematic cell division and elongation as well as root penetration (Hatung, 2004) and due to reduced cell division or cell enlargement caused by salinity stress (Hawker and Walker, 1978).
The reduced seedling FW and DW under salt stress conditions could be attributed to the physiological drought induced by the low water potential and osmotic adjustments as a result of increased ionic concentration in their cells, which result in deformation of macromolecules by disrupting their shell or bound water (Schwarz, 1985) and/or osmotic adjustment needed to keep root water potential lower than that of the external medium, energy must be expended to create such osmotic adjustment and this may lead to seedling growth reduction (Yeo, 1983) and/or might be attributed to the osmotic effect resulting from salt stress which causes disturbances in water balance and inhibits apical growth and internal hormonal imbalance (Younis et al., 2003 and Abo Shama and Hegazy, 2009) and/or inhibits cytokinins biosynthesis and hormonal unbalances, reducing water content and some plant nutrients uptake as well as biosynthesis of α-tocopherol, ascorbic acid and net photosynthetic rate accompanied with high respiration rate were also reported under stress conditions (Tripathi et al., 2007) and/or may be due to toxic effects unbalanced nutrient uptake by the seedlings (Hajibagheri et al., 1989) and/or decreases in water content (WC) have been communicated for many seedlings growing under salinity (Meloni et al., 2008).
The WC, although a convenient and widely used method of assessing plant water status, is not a useful indicator of turgor in salt-treated plants undergoing osmotic adjustment. In most plants, especially halophytes, the solute content of cells at high salinity is higher than in non-saline condition, due largely to accumulation of ions (e.g. Na\(^+\) and Cl\(^-\)) and organic solutes. Therefore, during the rehydration to establish WC, the higher solute content in salt-treated than in untreated cotyledons causes a greater water uptake in the former than the latter. Thus, this fact results in an apparently low RWC under salinity (Munns et al., 2006).
3. Peroxidase (POD) and Catalase (CAT) activity: The data illustrated in Figure (7) indicate that all applied salinity types increased significantly POD activity of sweet pepper seedling and high level of salinity was more effective in this respect. Moreover, POD activity under NaCl stress showed a marked increase followed by NaCl+ CaCl$_2$ (1:1) and CaCl$_2$.

Concerning the CAT activity (Figure, 8) under low level of all applied salinity types (2000 ppm) increased significantly CAT activity and NaCl+ CaCl$_2$ (1:1) proved to be more effective in this respect., followed by CaCl$_2$ and NaCl. On the other hand, increasing salinity levels to 4000 ppm decreased significantly CAT activity and the great reduction occurred under NaCl stress. Salt stress produced ROS is a common phenomenon which can interact with a number of cellular molecules and metabolites, thereby leading to a number of destructive processes causing cellular damage (Ashraf, 2009), cell signaling, gene regulation, senescence, programmed cell death, pathogen defense, and others (Gechev et al., 2006).

In this study, the antioxidant enzymes POD and CAT were increased under NaCl salinity (Figures, 7, 8) and further enhanced due to CaCl$_2$ treatment. These results are in agreement with those reported by Jaleel et al., (2007). The plants defend against these reactive oxygen species by induction of activities of certain antioxidative enzymes such as catalase (CAT), peroxidase (POD) (Mittova et al., 2003). Catalase is specific to a great extent for H$_2$O$_2$, and remove excess H$_2$O$_2$ before it can leak out into other parts of the cell (Ali and Alqurainy, 2006). The high concentration of H$_2$O$_2$ in tissues was mainly scavenged by CAT which led to a low level of H$_2$O$_2$, while low concentration of H$_2$O$_2$ was mainly scavenged by POD during the period of oxidation of relative substances. When POD and CAT were consistent and in harmony with one another, free radicals from ROS in plants could be kept at a low level which exerted the plant growth and metabolize naturally (Jiang, 1999). In addition, Turhan et al., (2006) proposed that the POD activity was increased coordinately in response to salt stress. In addition, Li (2009) revealed that, on tomato seedling the CAT activity increased under (100 mM NaCl), but the CAT activity decreased under 200-
Arafa, A.A. et al.

300 mM NaCl. Moreover, Wang et al. (2009) on alfalfa, found that salinity stress increased CAT activity. On the other hand, Noreen and Ashraf (2009) revealed that salt stress enhanced the activities of POD while, decreased the CAT activity in pea. Also, Hassanein et al. (2009) found that, activity level of POD enzyme progressively increased with increasing salinity levels, while the behavior of CAT activity showed an opposite response. In addition, Gadalla (2009) found that NaCl reduced the activity of CAT and POD.

![Figure (7): Peroxidase activity (POD) (unit/g FW) of seedling sweet pepper as affected by salinity (NaCl, CaCl₂ and their combinations) after 14 days from sowing.](image)

![Figure (8): Catalase activity (CAT) (unit/g FW) of seedling sweet pepper as affected by salinity (NaCl, CaCl₂ and their combinations) after 14 days from sowing.](image)

5. Photosynthetic pigments concentrations

The data illustrated in Figures (9-12) clearly show that low salinity level (2000 ppm) of all applied salinity types (NaCl, CaCl₂ and their combinations 1:1 (w:w)) caused a high significant increase in the photosynthetic pigments concentrations (chlorophyll a, b and total chlorophylls as well as carotenoids). In addition, NaCl+CaCl₂ (1:1) caused a greater increase in photosynthetic pigments concentrations followed by CaCl₂
and NaCl. The stimulating effects of low salinity level may be resulted from the effect of low concentration of Cl⁻ on photosynthesis and enzymes activity and chloride acts a cofactor of an NH₂OH sensitive, Mn-containing, O₂-evolving enzyme (Kelley and Izawa, 1978) and Cl⁻ was involved in the splitting of water molecules in photosystem II (Izawa et al., 1969). On the other hand, photosynthetic pigments concentrations decreased gradually with increasing salinity levels from 2000 to 4000 ppm. The great reduction in photosynthetic pigments occurred under NaCl at high salinity levels (4000 ppm). While, CaCl₂ at 4000 ppm increased significantly the total carotenoids as compared with other salinity types. These results are in agreement with those recorded by Parida et al. (2004) who reported that photosynthetic rate increased at low salinity level and decreased at the higher ones.

Figure (9): Chlorophyll a concentration (mg/g FW) of seedling sweet pepper as affected by salinity (NaCl, CaCl₂ and their combinations) after 14 days from sowing.

Figure (10): Chlorophyll b concentration (mg/g FW) of seedling sweet pepper as affected by salinity (NaCl, CaCl₂ and their combinations) after 14 days from sowing.
The reduction in photosynthetic pigments concentrations under high salinity levels may be due to inhibitory effect of chloride on the activity of Fe containing enzymes, cytochrome oxidase which may decrease the rate of chlorophyll, biosynthesis and their accumulation (Helaly et al., 1984) and/or enhancing the activity of chlorophyll degrading enzyme chlorophyllase (Mishra and Sharma, 1994) and/or oxidation of chlorophyll and decreased its concentration (Pell and Dann, 1991) and/or the toxic action of NaCl on the biosynthesis of pigments, increasing their degradation and/or maintaining damage of the chloroplast thylakoid (Hashem, 2000).

Concerning CaCl\textsubscript{2} at 4000 ppm it is observed that, carotenoids concentration was increased as compared to control (Figure 12). These results may be due to the fact that Ca\textsuperscript{2+} play a critical role in light harvesting complex assembly and function (Munné-Bosch et al., 1999) and/or antioxidants under salt stress (Vaidyanathan et al. 2003).
It could be concluded that low salinity level irrespective its type had a stimulative effect on the studied parameters and the higher ones showed the opposite effect in this respect.

لمقارنة تأثير ملوحة كلوئيدي الصوديوم والكالسيوم وكذلك مخلوطهما على إنبات
ونمو بادرات الفلفل الحلو أجريت تجربتان منفصلتان في معمل قسم النبات الزراعى كلية
الزراعة جامعة المنصورة مصر عام 2008. وأوضحت النتائج إلى حدوث زيادة معنوية
في كل من نسبة الانتشار، دليل نسبة الانتشار، الوزن الطازج والجاف وطول البادرات،
المحتوى المائي للبادرات، نشاط إنزيم الكاتاليز وذلك تركز صبغات النبات الضوئى
كلوروفيل أ، ب والكلوروفيل الكلي (الكاروتينات) وذلك تحت مستوي الملوحة المنخفض
(2000 جزء في المليون من كل من كلوئيدي الصوديوم والكالسيوم وكذلك مخلوطهما بنسبة
1:1). (وزن: وزن)

إدي زيادة تركيز الملح في المحلول المغذي الي حدوث نقص معنوي في كل
الصفات السابقة، وكان كلوئيدي الصوديوم 4000 جزء في المليون الأكثر تأثراً. ولكن كان
النقص غير معنوي بالنسبة للمحتوى المائي للبادرات. بالإضافة إلى ذلك إدي كلوئيدي
الكالسيوم بتركيز 4000 جزء في المليون إلى حدوث زيادة معنوية بالنسبة لتركيز
الكروتتينات وذلك بالمقارنة بالأملاح الأخرى.
بينما إدي زيادة تركيز الملح من 2000 إلي 4000 جزء في المليون إلي زيادة نشاط
إنزيم البيروكسيديز. علاوة علي ذلك كان كلوئيدي الصوديوم الأكثر تأثراً يليه مخلوط
الأملاح (1:1).
